

Homework 1

Jacob van de Lindt

Setup

The magnetic field around the unstable pinch can be given by

$$B(\theta) = \frac{C_0}{2} + \sum_{m=1}^{\infty} \{ C_m \cos(m\theta) + S_m \sin(m\theta) \}$$

$$\hat{J}_p = \begin{cases} \hat{z} J_p, & r < a \\ 0, & r > a \end{cases}$$

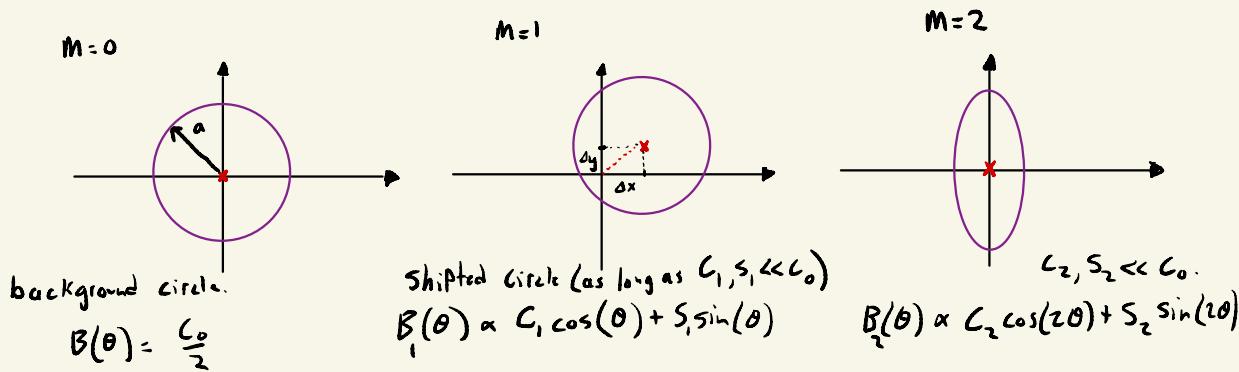

The Fourier components are given by:

$$C_m = \frac{1}{\pi} \int_0^{2\pi} B(\theta) \cos(m\theta) d\theta \approx \frac{1}{\pi} \sum_j B(\theta_j) \cos(m\theta_j) \Delta\theta_j$$

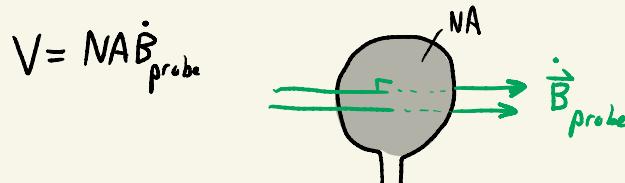

$$S_m = \frac{1}{\pi} \int_0^{2\pi} B(\theta) \sin(m\theta) d\theta \approx \frac{1}{\pi} \sum_j B(\theta_j) \sin(m\theta_j) \Delta\theta_j$$

where the sums are approximations made by discrete b-dot probes at position θ_j separated by an angular separation of $\Delta\theta_j$.

The first few of these modes are sketched below:

The B-dot probe's working principle is to measure the change in flux through it. Assuming the probe's area remains constant, then it measures \dot{B} :

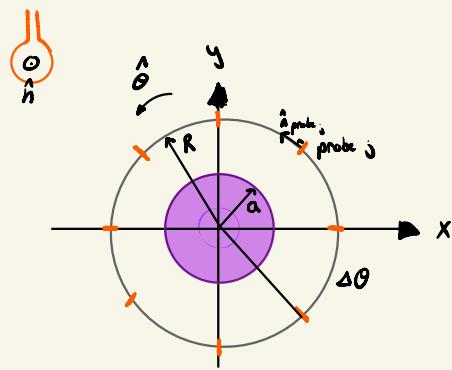

Assume the Z pinch is initially stable: $B_0(\theta) = \frac{C_0}{2}$, $B_{m>0} = 0$. Then at $t=0$, the initial condition on all higher modes $B_{m>0} = 0$ at $t=0$. Then,

$$B_{\text{probe}} = \sum_{t_i} \frac{V_{\text{probe}}}{N A} \Delta t, \text{ where we assume we can digitally sample in time at } \Delta t \ll t_{\text{instability}},$$

the characteristic instability timescale. So, we can now measure B_{probe} through each b-dot probe by knowing each Voltage V_s at time $s \Delta t$.

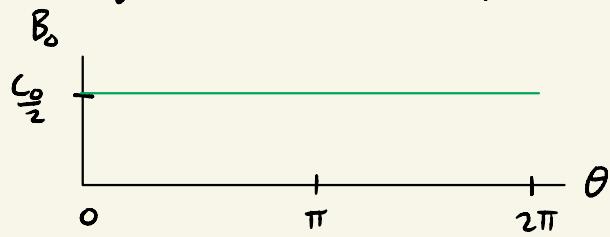

Now we are set up to measure the different modes by discretely placing B-dot's around the Z-pinch with azimuthal spacing $\Delta\theta$, the \hat{n} probe normal vector aligned with $\hat{\theta}$.

General depiction: probes are aligned so $\hat{n} \parallel \hat{\theta}$.

Question 1

Only 1 probe is required because B_0 is independent of θ : so measuring at any θ will do.

This also jibes with the Nyquist frequency limit: our spatial sampling must be greater than twice the angular mode. So, $2^*0=0$, so we need ≥ 2 probe to satisfy the Nyquist inequality. $M=0$ is a Sausage instability: J is constricted or broadened to move through a changing area normal to its flow.

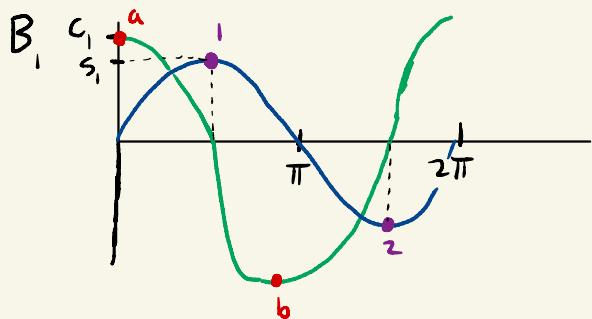

$$C_0 = \frac{1}{\pi} \int_0^{2\pi} B_0 \cos(\theta) d\theta = \frac{1}{\pi} (B_0 2\pi) = 2B_0$$

$$\frac{C_0}{2} = B_0.$$

$C_0 = 2B_0$ so the first fourier coefficient can be determined based on the b-dot measurement.

Question 2 • What is the minimal arrangement of b-dot probes to necessary to sense the $M=1$ displacement mode?

plot for $S_1=0$

Nyquist requirement is one samples at spatial frequency K greater than twice the spatial frequency of the largest spatial frequency we want to measure. Here for $M=1$, we need to sample at minimum $1+2+1=3$ to resolve a spatial frequency of 2π radians per cycle.

For example: the red probe locations $a, \theta=0$ and $b, \theta=\pi$ show that they can resolve the cos component of B_1 . But at these locations sine is always zero, so probes a and b are insensitive to the sine component of B_1 .

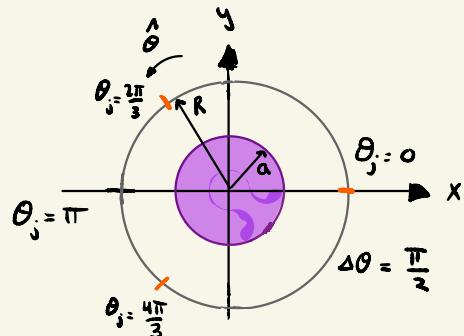

The purple probe locations $1, \theta=\frac{\pi}{2}$ and $2, \theta=\frac{3\pi}{2}$ are insensitive to the cosine component of B_1 and can resolve the sin components. So the probes are just not enough.

So we need 3 probes at $\theta=0, \frac{2\pi}{3}, \frac{4\pi}{3}$ to resolve the $M=1$ mode

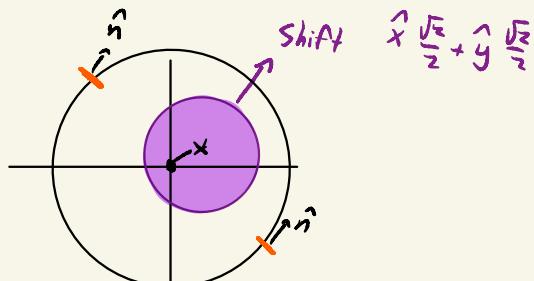

The Fourier components are:

$$C_1 \approx \frac{1}{\pi} \sum_j B(\theta_j) \cos(2\theta_j) \Delta\theta_j$$

$$S_1 \approx \frac{1}{\pi} \sum_j B(\theta_j) \sin(2\theta_j) \Delta\theta_j$$

Needing 3 probes makes sense. $M=1$ is a shift, so if we only had two probes, π apart, then if the plasma shifts parallel to the normal vector of the two b-dots, we would miss its motion:

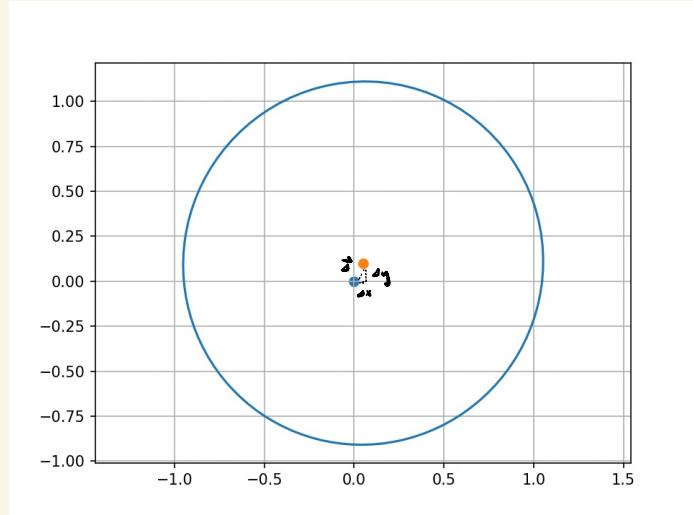

Two probes π apart miss motion parallel to their normal vectors \hat{n} .

As an example, I will define $B_\theta(\theta) = \frac{M_0 I}{2\pi R} \frac{1}{[(\sin \theta - \frac{\Delta y}{R})^2 + (\cos \theta - \frac{\Delta x}{R})^2]^{1/2}}$
 which is an $M=1$ plasma perturbation where the plasma column has been shifted
 by $x = \Delta x$ and $y = \Delta y$. Let $\frac{M_0 I}{2\pi} = 1$, $R = 1$, $\Delta x = 0.05$, $\Delta y = 0.1$

This produces the following field:

$$B_{\theta y}$$

$$B_{\theta x}$$

Now imagine I have 3 probes at $\theta = 0, \frac{2\pi}{3}, \frac{4\pi}{3}$

The probes would measure (based on my above function)

$$\theta_1 = 0 \quad B(0) = 1.0468$$

$$\theta_2 = \frac{2\pi}{3} \quad B\left(\frac{2\pi}{3}\right) = 1.0604$$

$$\theta_3 = \frac{4\pi}{3} \quad B\left(\frac{4\pi}{3}\right) = 0.8995$$

Now I can numerically reconstruct C_1 and S_1 with $\Delta\theta_j = \frac{2\pi}{3}$:

$$C_1 \approx \frac{1}{\pi} \sum_j B(\theta_j) \cos(2\theta_j) \Delta\theta_j = 0.0445 \quad (\text{Very close to the actual } C_1 = 0.05)$$

$$S_1 \approx \frac{1}{\pi} \sum_j B(\theta_j) \sin(2\theta_j) \Delta\theta_j = 0.0928$$

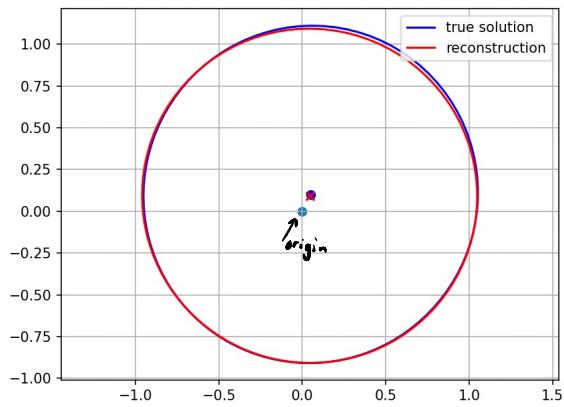

Using these, along with $C_0 = 2 \frac{M_0 I}{2\pi R} = 2$ I can plug these into my formula:

$$B(\theta) = \frac{C_0}{2} + C_1 \cos(2\theta) + S_1 \sin(2\theta) \quad \text{and plot this versus the true function above:}$$

$$\text{The predicted shift is } \vec{d} = \frac{2C_1}{C_0} \vec{x} + \frac{2S_1}{C_0} \vec{y}.$$

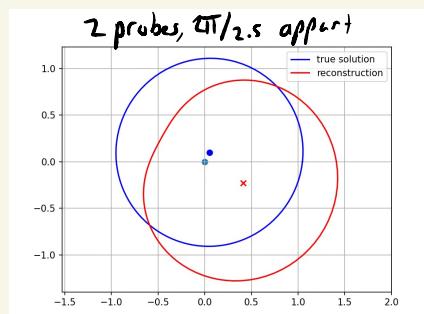

3 probes: closely predicts shift (dark blue dot, red x)

As you can see, the reconstruction nearly exactly predicts the center of the shift (red x overlaps dark blue circle). The light blue circle is 0,0 for reference.

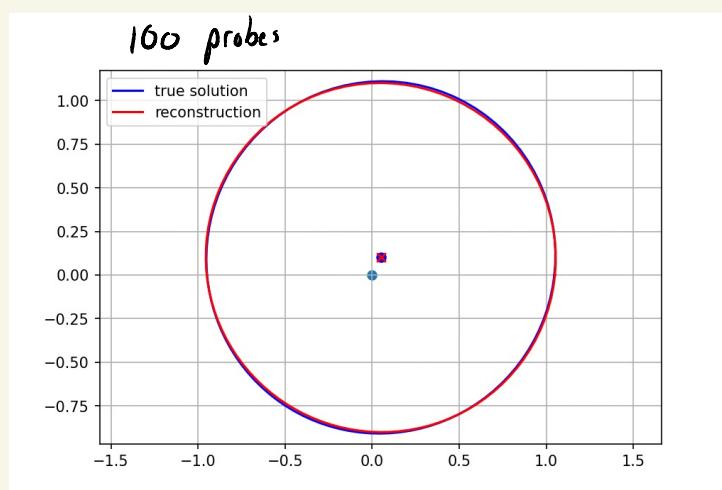

If I only had 2 probes, say $\frac{2\pi}{2.5}$ apart instead of $\frac{2\pi}{3}$, I get

2 probes: not enough!

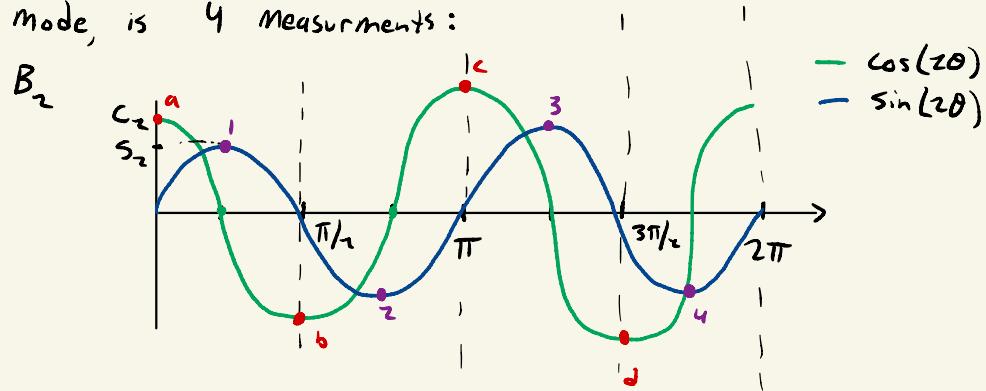

Completely wrong displacement direction.

If I have 100 probes: I do slightly better than three. Three is enough for $m=1$.

Question 3: What is the minimal number of b-dot probes to sense the $M=2$ (elongation) mode?

The same logic holds. We need, for both the sin and cos components, twice as many measurements as the spatial frequency which we want to measure. Which, for the $M=2$ mode, is 4 measurements:

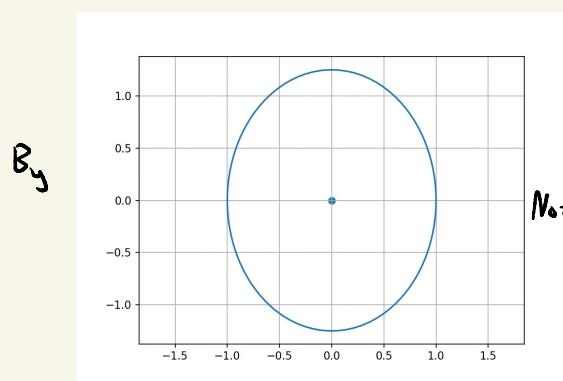

As can be seen, we need greater than 4 probe locations, $a, b, c, d, 1, 2, 3, 4$ to measure both the sin and cos components of B_z . $2^*(m=2)+1 = 5$ probes

So: Use 5 probes spaced $\frac{2\pi}{5}$ s apart to measure $B_z(\theta)$.

As an example, I will create the elongated reference field:

$$B_\theta(\theta) = \frac{\mu_0 I}{2\pi R} \frac{1}{[(\sin \theta)^2 + (\cos \theta)^2]^{1/2}}$$

which looks like:

Note $C_0 = 2\sqrt{B_\theta(0)B_\theta(\pi)}$
 $C_0 = 2.236$,
 which could be measured as I described earlier.

Now imagine I have 5 probes at $\theta = 0, \frac{2\pi}{5}, \frac{4\pi}{5}, \frac{6\pi}{5}, \frac{8\pi}{5}$.

The probes would measure (based on my above function):

See next page

$$\begin{aligned}\theta_1 &= 0 & B(\theta_1) &= 1 \\ \theta_2 &= \frac{2\pi}{5} & B(\theta_2) &= 1.21 \\ \theta_3 &= \frac{4\pi}{5} & B(\theta_3) &= 1.068 \\ \theta_4 &= \frac{6\pi}{5} & B(\theta_4) &= 1.068 \\ \theta_5 &= \frac{8\pi}{5} & B(\theta_5) &= 1.21\end{aligned}$$

Now I can numerically reconstruct C_2 and S_2 with $\Delta\theta_j = \frac{2\pi}{5}$:

$$C_2 \approx \frac{1}{\pi} \sum_j B(\theta_j) \cos(2\theta_j) \Delta\theta_j = -0.1239$$

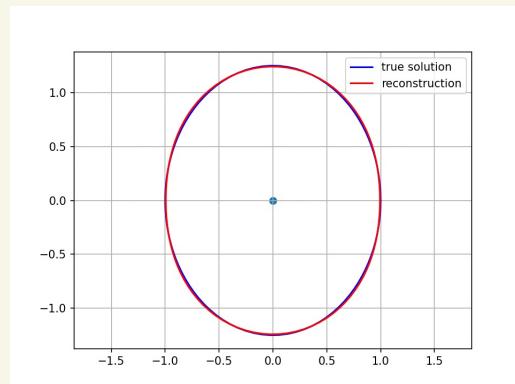

$$S_2 \approx \frac{1}{\pi} \sum_j B(\theta_j) \sin(2\theta_j) \Delta\theta_j = 1.413$$

Using these, along with $C_0 = 2.236$

I can plug these into my formula:

$B(\theta) = \frac{C_0}{2} + C_2 \cos(2\theta) + S_2 \sin(2\theta)$ and plot this versus the true function above:

These yield the following:

which is a very good approximation.

So: Use 5 probes spaced $\frac{2\pi}{5}$ s apart to measure $B_2(\theta)$.

Question 4

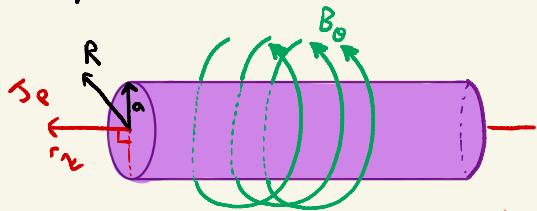

For higher order modes, the Nyquist limit still holds. So, for Mode M , I need $2M+1$ evenly spaced b-dots to detect the mode with no aliasing, etc.

Question 5

If the assumption of uniform current density is removed, do my results still hold?

Now I have

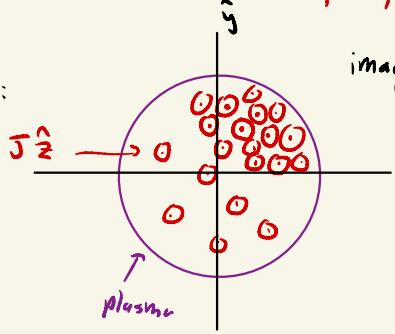

\vec{z} -pinch

Let \vec{J} be in \hat{z} and vary in r, θ as $f(r, \theta)$.

$$J_p = \begin{cases} \hat{z} f(r, \theta) J_p, & r \leq a \\ 0, & r > a \end{cases}$$

For example:

imagine if J_z^h was localized in the upper right as shown. The cylindrical symmetry of the problem is broken, and we can expect \vec{B} outside the plasma to be $\vec{B} = B_r \hat{r} + B_\theta \hat{\theta}$ by symmetry breaking.

So, our b-dots, although still on a loop $\oint \vec{B} \cdot d\vec{l} = \mu_0 I_{enc}$ fully surrounding I_{enc} , we can no longer say $\vec{B} \cdot d\vec{l} = B_r r d\theta$, instead $\vec{B} \cdot d\vec{l} = B_\theta r d\theta$.

So, we can only infer information about $B_\theta \hat{\theta}$ from our b-dots (assuming we don't align them to the local \vec{B} , and leave their normal vectors pointing in $\hat{\theta}$), and not the total \vec{B} .
